Workshop: Advances in Numerical Methods for Economics Washington, D.C.

June 28, 2013

## Motivation: Long-Term Debt

Recent literature on quantitative corporate finance (Hennessy and Whited (2005)) considers only short-term debt

Largely due to computational reasons!

This is not a costless simplification:

1. No agency costs: bondholders know investment and debt when they lend
2. Built-in maturity mismatch and hence rollover risk
3. Hard to generate large credit spreads

## Main effects:

1. Reduces leverage (as in Leland and Toft (1996)), generates more default, and higher credit spreads
2. Amplifies response of investment to changes in credit spreads

## Motivation: Uncertainty Shocks

Introduce uncertainty shocks (Bloom (2009)) to replicate empirical results on Q-theory:

1. Tobin's $Q$ is a sufficient statistic for investment (Abel (1979) and Hayashi (1982))
2. Doesn't work well empirically
3. Models appeal to measurement error (Erickson and Whited (2001), Eberly et al. (2008))
4. Q-theory works better with bond prices or credit spreads (Gilchrist and Zakrajsek (2008), Philippon (2009))

## Why Do Uncertainty Shocks Help?

Shock to Productivity

1. $\nearrow$ in productivity $\Rightarrow \searrow$ in the probability of default, $\searrow$ credit spreads
2. $\nearrow$ in productivity $\Rightarrow \nearrow$ in investment, $\nearrow$ in $Q$

Generates: $\operatorname{Corr}(I / K, Q)>0, \operatorname{Corr}(I / K$, spread $)<0$

Shock to Volatility

1. $\nearrow$ in volatility $\Rightarrow \nearrow$ in the probability of default, $\nearrow$ credit spreads
2. $\nearrow$ in volatility $\Rightarrow \searrow$ in investment, $\nearrow$ in $Q$ (growth option value vs assets in place)

Generates: $\operatorname{Corr}(I / K, Q)<0, \operatorname{Corr}(I / K$, spread $)<0$

## Contribution

This paper:

1. Extends a standard neoclassical model of financing and investment to incorporate long-term debt and stochastic volatility
2. Explores the quantitative impacts of these new ingredients in a calibrated model

Findings:
Long-term debt and stochastic volatility lead to:

1. Lower and more volatile leverage
2. Higher probability of default, and higher credit spreads
3. An increase in the explanatory power of credit spreads on $i / k$
4. A decrease in the explanatory power of Tobin's $Q$ on $i / k$
(compared to model with one-period debt and deterministic volatility of profits)

## Environment

This model builds on Gomes and Schmid (2009)

Model Ingredients:

- Dynamic, partial equilibrium, exogenous pricing kernel
- Financial decisions: debt and equity issuance, default
- Real decision: investment

Departure from literature:

- Shocks to volatility of productivity
- Long-term debt

## Environment

Time:

- Time is discrete
- Problem is infinite horizon

Uncertainty:

- Aggregate Shocks: productivity $z_{a}$
- Idiosyncratic Shocks: productivity $z_{i}$
- Idiosyncratic Shocks: volatility $\sigma$
$\Rightarrow$ Tomorrow's shock $z_{i}^{\prime}$ has volatility $\sigma$
$\Rightarrow$ Shock $\sigma$ today has an impact only on tomorrow's realizations of $z_{i}$

Exogenous State Vector: $s \equiv\left(z_{a}, z_{i}, \sigma\right)$

## Firm Problem

Firms:

- Produce: $\pi(k, s)$, using capital $k$
- Invest in capital $k$
- Irreversible investment $(i \geq 0)$, and linear adjustment cost $\phi_{+}$for $i>0$
- Long-term (exponentially decaying) debt: stock $b$
- Issue equity: $d<0$
- Default if equity $V<0$
- Taxes: Profits -net of interest expenses- are taxed at rate $\tau$

Equity Value:
Firms maximize the expected discounted stream of dividends

$$
V(k, b, s)=\max _{k^{\prime}, b^{\prime}} \quad d+\mathbb{E}\left[M\left(s, s^{\prime}\right) \max \left(0, V\left(k^{\prime}, b^{\prime}, s^{\prime}\right)\right)\right]
$$

## Firm Problem

Budget constraint:

$$
\tilde{d}=\underbrace{(1-\tau) \pi(k, s)}_{\text {After-Tax Profits }}+\underbrace{\tilde{q} \ell}_{\text {New Loan }}-\underbrace{\delta_{b} b}_{\text {Debt Repayment }}-\underbrace{i}_{\text {Investment }}-\underbrace{\phi_{+} i}_{\text {Cost of Investment }}
$$

Dividends or Equity Issuance:

$$
d=(1+\underbrace{\lambda \mathbf{1}_{\{\tilde{d}<0\}}}_{\text {Issuance Cost }}) \tilde{d}
$$

New Loan: (Sells for price $q$ )

$$
\ell=b^{\prime}-\left(1-\delta_{b}\right) b
$$

## Lender Problem

Lenders: $(q=$ Price of a $\$ 1$ loan $)$

$$
\begin{aligned}
q_{t}= & \mathbb{E}_{t}\left[M_{t, t+1}\left(\delta_{b} \mathbf{1}_{t+1}+\xi \frac{k_{t+1}}{b_{t+1}}\left(1-\mathbf{1}_{t+1}\right)\right)\right] \\
& +\mathbb{E}_{t}[M_{t, t+2}(\underbrace{\delta_{b}\left(1-\delta_{b}\right)}_{\text {Coupon }} \mathbf{1}_{t+2}+\underbrace{\xi k_{t+2}}_{\text {Default Payoff }} \underbrace{\frac{\left(1-\delta_{b}\right)}{b_{t+2}}}_{\text {Claim }} \underbrace{\mathbf{1}_{t+1}\left(1-\mathbf{1}_{t+2}\right)}_{\text {Default Event }})]
\end{aligned}
$$

$$
+\ldots
$$

As an infinite sum:

$$
\begin{aligned}
q_{t}= & \sum_{s=1}^{\infty} \mathbb{E}_{t}\left[M_{t, t+s}\left(\delta_{b}\left(1-\delta_{b}\right)^{s-1} \mathbf{1}_{t+s}\right)\right] \\
& +\sum_{s=1}^{\infty} \mathbb{E}_{t}\left[M_{t, t+s}\left(\xi \frac{k_{t+s}}{b_{t+s}}\left(1-\delta_{b}\right)^{s-1} \mathbf{1}_{t+s-1}\left(1-\mathbf{1}_{t+s}\right)\right)\right]
\end{aligned}
$$

## Lender Problem

Recursive Formulation:
Given firms' policies, $\left(k^{\prime}, b^{\prime}\right)=\left(g_{k}(k, b, s), g_{b}(k, b, s)\right)$, the loan price satisfies,

$$
\begin{aligned}
& q\left(k^{\prime}, b^{\prime}, s\right)=\mathbb{E}\left[M\left(s, s^{\prime}\right)\left(\delta_{b}+\left(1-\delta_{b}\right) q\left(k^{\prime \prime}, b^{\prime \prime}, s^{\prime}\right)\right) \mathbf{1}_{\left\{v^{\prime} \geq 0\right\}}\right] \\
&+\mathbb{E}\left[M\left(s, s^{\prime}\right)\left(1-\delta_{b}\right) \xi \frac{k^{\prime}}{b^{\prime}}\left(1-\mathbf{1}_{\left\{v^{\prime} \geq 0\right\}}\right)\right]
\end{aligned}
$$

Price Schedule Inclusive of Tax Subsidy: $\tilde{q}=\tilde{q}(q ; \tau)$

$$
\tilde{q}=\sum_{t=1}^{\infty}\left(\frac{1}{1+(1-\tau) c(q)}\right)^{t} \delta_{b}\left(1-\delta_{b}\right)^{t-1}=\frac{1}{1+(1-\tau)\left(q^{-1}-1\right)}
$$

## Recursive Formulation of the Firm Problem

Recursive Formulation of the Firm Problem:
Given the loan price schedule $q\left(k^{\prime}, b^{\prime}, s\right)$, firms solve the following program,

$$
V(k, b, s)=\max _{k^{\prime}, b^{\prime}} d+\mathbb{E}\left[M\left(s, s^{\prime}\right) \max \left(0, V\left(k^{\prime}, b^{\prime}, s^{\prime}\right)\right)\right]
$$

subject to,

$$
\begin{aligned}
d & =\left(1+\lambda \mathbf{1}_{\{\tilde{d}<0\}}\right)\left\{(1-\tau) \pi(k, s)+\tilde{q}\left(k^{\prime}, b^{\prime}, s\right) \ell-\delta_{b} b-i\left(1+\phi_{+}\right)\right\} \\
i & =k^{\prime}-\left(1-\delta_{k}\right) k \geq 0 \\
\ell & =b^{\prime}-\left(1-\delta_{b}\right) b
\end{aligned}
$$

## Recursive Equilibrium

Recursive Competitive Equilibrium:
A recursive competitive equilibrium consists of a loan price schedule $q\left(k^{\prime}, b^{\prime}, s\right)$, a value function $V(k, b, s)$, and optimal decision rules $g_{k^{\prime}}(k, b, s)$ and $g_{b^{\prime}}(k, b, s)$, such that

1 Firms: The value function $V(k, b, s)$ solves the firm problem. The associated optimal decision rules for the firm are denoted by $k^{\prime}=g_{k^{\prime}}(k, b, s)$ and $b^{\prime}=g_{b^{\prime}}(k, b, s)$

2 Lenders: The loan price schedule $q\left(k^{\prime}, b^{\prime}, s\right)$ satisfy the lenders Euler equation

## Computational Considerations

Solving the Model:

1. Inner loop: Given bond prices, solve firm problem by VFI (with PFI)
2. Outer loop: Update bond prices given firm's decisions

Computational Issues:
Time-consuming given large number of states
Hard to achieve full convergence with long-term debt (bc non convex constraint set)

- Chatterjee and Eyigungor (2011) provide an algorithm that performs well
- We extended their algorithm to incorporate endogenous investment
- Makes computation even slower!

## Algorithm

$\underline{\text { Transforming the model: }}$

1. Add small, continuous i.i.d. shock to profits $m \sim$ truncated $\mathcal{N}\left(0, \sigma_{m}^{2}\right), \quad$ with $\sigma_{m}=0.04$
2. Add a small dividend smoothing motive: Firms maximize PDV of $h(d)=d-\kappa d^{2}, \quad$ with $\kappa=0.01$

Algorithm:

1. Requires exact computation of default thresholds
2. Use very slow relaxation for bond price updates,

$$
q^{k+1}=\zeta q^{k}+(1-\zeta) q^{\text {new }}, \quad \text { with } \zeta=0.95
$$

## Modified Firm Problem

## Modified Firm Problem:

Given the loan price schedule $q\left(k^{\prime}, b^{\prime}, s\right)$, firms solve,

$$
V(k, b, s)=\max _{k^{\prime}, b^{\prime}} \quad h(d)+\mathbb{E}\left[M\left(s, s^{\prime}\right) \max \left(0, V\left(k^{\prime}, b^{\prime}, s^{\prime}\right)\right)\right]
$$

subject to,

$$
d=\left(1+\lambda \mathbf{1}_{\{\tilde{d}<0\}}\right)\left\{(1-\tau)(\pi(k, s)+m)+\tilde{q}\left(k^{\prime}, b^{\prime}, s\right) \ell-\delta_{b} b-i\left(1+\phi_{+}\right)\right\}
$$

where $m$ is the i.i.d. cash flow shock

## Numerical details

Practical implementation:

1. State Space: $\left(k, b, z_{a}, z_{i}, \sigma\right)$ with $\left(96^{*} 96^{*} 4^{*} 16^{*} 2\right)=1.2 m$ grid points
2. Implementation: CUDA code run on NVIDIA Fermi card Typical run is $\approx 5$ hours (Speed up 500x)

Monte Carlo Simulations:

1. Simulate a panel of 10,000 firms for 200 periods (drop first 5 periods)
2. Compute statistics/run regressions with simulated data

## Calibration: Aggregate Exogenous States

Productivity Process: Follows an $\operatorname{AR}(1)$ process

$$
\log z_{a}^{\prime}=\rho_{a} \log z_{a}+\sigma_{a} \epsilon_{a}^{\prime}
$$

Discretized as a Markov Chain, with $\rho_{a}=0.85, \sigma_{a}=0.02$

Stochastic Discount factor:

$$
M\left(z_{a}, z_{a}^{\prime}\right)=\beta e^{-\gamma_{0}\left(\log z_{a}^{\prime}-\rho_{a} \log z_{a}\right)}
$$

Set $\gamma_{0}=15$
Note that $\mathbb{E}_{s^{\prime} \mid s}\left[M\left(s, s^{\prime}\right)\right]=\beta$, so term structure is flat

## Calibration: Idiosyncratic Exogenous States

Idiosyncratic Productivity Process: Follows an $\mathrm{AR}(1)$ process

$$
\log z_{i}^{\prime}=\rho_{i} \log z_{i}-\sigma^{2} / 2+\sigma \epsilon_{i}^{\prime}
$$

Discretized as a Markov Chain, with $\rho_{i}=0.9$

Idiosyncratic Volatility Process: Follows a Markov chain with 2 states

$$
\sigma \in\left\{\sigma_{L}, \sigma_{H}\right\}
$$

Set $\sigma_{L}=0.10, \sigma_{H}=0.25$, with transition matrix $\Gamma_{\sigma \sigma^{\prime}}$ given by

$$
\Gamma=\left[\begin{array}{ll}
0.9 & 0.1 \\
0.1 & 0.9
\end{array}\right]
$$

## Calibration: Real Side

Parameters chosen to match means of the data: Tobin's $Q, i / k$, and $\pi / k$

Profits:

$$
\pi(k, s)=z_{a} z_{i} k^{\alpha}-f
$$

Set $\alpha=0.4, f=0.92, \delta_{k}=0.14$

Adjustment Cost:

$$
\phi(i, k)=\phi_{+} i \quad \text { for } i>0
$$

Set $\phi_{+}=0.05$

## Parameters

|  | Parameter | Model | Description |
| :--- | :---: | :---: | :--- |
| Preference | $\beta$ | 0.98 | Subjective discount rate |
|  | $\alpha$ | 0.4 | Production parameter |
| Technology | $\phi_{+}$ | 0.05 | Cost of positive investment |
|  | $f$ | 0.92 | Fixed cost of operation |
|  | $\delta_{k}$ | 0.14 | Capital depreciation rate |
|  | $\delta_{b}$ | 0.2 | Exponential decay for debt |
|  | $\lambda$ | 0.25 | Linear cost of issuing equity |
| Institution | $\xi$ | 0.80 | Recovery rate in bankruptcy |
|  | $\tau$ | 0.20 | Average corporate tax rate |
|  | $\rho_{a}$ | 0.85 | Autocorrelation of $z_{a}$ |
| Uncertainty | $\sigma_{a}$ | 0.02 | Volatility of $z_{a}$ |
|  | $\rho_{i}$ | 0.90 | Autocorrelation of $z_{i}$ |
|  | $\sigma_{L}$ | 0.10 | Low Volatility of $z_{i}$ |
|  | $\sigma_{H}$ | 0.25 | High Volatility of $z_{i}$ |

## Definition: Variables

## Real Policies:

Tobin's $Q$

$$
\begin{aligned}
& Q=\frac{V(k, b, s)+b^{\prime}}{k^{\prime}} \\
& \frac{i}{k}=\frac{k^{\prime}-\left(1-\delta_{k}\right) k}{k}
\end{aligned}
$$

Investment Rate

Profitability

$$
\frac{\pi}{k}=\frac{z k^{\alpha}-f+m}{k}
$$

Financial Policies:

Leverage
$\frac{b^{\prime}}{k^{\prime}}$
Credit Spreads

$$
C S=\delta_{b} q\left(k^{\prime}, b^{\prime}, s\right)^{-1}-\beta^{-1}+1-\delta_{b}
$$

Default

$$
I^{D F}=\mathbf{1}_{\{V(k, b, s)<0\}}
$$

## Where is the Effect Stronger?

| Model Specification | $\log (c)$ | $\log (Q)$ | $R^{2}$ |
| :--- | :---: | :---: | :---: |
| Data | -0.035 |  | 0.054 |
|  |  | 0.051 | 0.064 |
|  | -0.034 | 0.002 | 0.062 |
| (4) Stochastic $\sigma$ | -0.108 |  | 0.041 |
| 5 period |  | 0.222 | 0.086 |
|  | 0.017 | $\mathbf{0 . 2 4 0}$ | 0.087 |
| Far from default: | 0.304 | $\mathbf{0 . 7 8 2}$ | 0.135 |
| Close to default: | -0.034 | $\mathbf{0 . 0 9 8}$ | 0.092 |

## Conclusion

We propose a neoclassical investment model with stochastic volatility in firms' productivity shocks and long-term defaultable debt

In our calibrated model, we find that these new ingredients:

1. Reduce the mean leverage, increase the probability of default
2. Increases the explanatory power of credit spreads on $i / k$
3. Decreases the explanatory power of Tobin's $Q$ on $i / k$

Model extensions:

1. Experiment with idiosyncratic 'disaster' shocks (compare to stochastic volatility)
2. Use model to measure agency costs of debt (induced by multi-period maturity)

## Questions.
